Untraceable Electronic Mail, Return addresses, and Digital Pseudonyms

David L. Chaum
University of California, Berkeley

Abstract

A technique based on public key cryptography is presented that allows
an electronic mail system to hide who a participant communicates with
as well as the content of the communication - in spite of an unsecured
underlying telecommunication system. The technique does not require a
universally trusted authority. One correspondent can remain anonymous
to a second, while allowing the second to respond via an untraceable
return address.

The technique can also be used to form rosters of untraceable digital
pseudonyms from selected applications. Applicants retain the
exclusive ability to form digital signatures corresponding to their
pseudonyms. Elections in which any interested party can verify that
the ballots have been properly counted are possible if anonymously
mailed ballots are signed with pseudonyms from a roster of registered
voters. Another use allows an individual to correspond with a
record-keeping organization under a unique pseudonym which appears in
a roster of acceptable clients.
Introduction

Cryptology is the science of secret communication. Cryptographic techniques have been providing secrecy of message content for thousands of years [3]. Recently some new solutions to the "key distribution problem" (the problem of providing each communicant with a secret key) have been suggested [2,4], under the name of public key cryptography. Another cryptographic problem "the traffic analysis problem" (the problem of keeping confidential who converses with whom and when they converse), will become increasingly important with the growth of electronic mail. This paper presents a solution to the traffic analysis problem that is based on public key cryptography. Baran has solved the traffic analysis problem for networks [1], but requires each participant to trust a common authority. In contrast, systems based on the solution advanced here can be compromised only by subversion or conspiracy of all of a set of authorities. Ideally, each participant is an authority.

The following two sections introduce the notation and assumptions. Then the basic concepts are introduced for some special cases involving a series of one or more authorities. The final section covers general purpose mail networks.

Notation

Someone becomes a user of a public key cryptosystem (like that of Rivest, Shamir, and Adleman [5]) by creating a pair of keys $K$ and $\text{Inv}(K)$ from a suitable randomly generated seed. The public key $K$ is made known to the other users or anyone else who cares to know it; the private key $\text{Inv}(K)$ is never divulged. The encryption of $X$ with key $K$ will be denoted $K(X)$, and is just the image of $X$ under the mapping implemented by the cryptographic algorithm using key $K$. The increased utility of these algorithms over conventional algorithms results because the two keys are inverses of each other, in the sense that

$$\text{Inv}(K)(K(X)) = K(\text{Inv}(K)(X)) = X.$$  

A message $X$ is "sealed" with a public key $K$ so that only the holder of the private key $\text{Inv}(K)$ can discover its content. If $X$ is simply encrypted with $K$, then anyone could verify a guess that $Y = X$ by checking whether $K(Y) = K(X)$. This threat can be eliminated by attaching a large string of random bits $R$ to $X$ before encrypting. The sealing of $X$ with $K$ is then denoted $K(R, X)$. A user "signs" some material $X$ by prepending a large constant $C$ (all zeros, for example) and then encrypting with its private key, denoted $\text{Inv}(K)(C, X) = Y$. Anyone can verify that $Y$ has been signed by the holder of $\text{Inv}(K)$ and determine the signed matter $X$, by forming $K(Y) = C$, $X$ and checking for $C$.

Assumptions
The approach taken here is based on two important assumptions:

1. No one can determine anything about the correspondences between a set of sealed items and the corresponding set of unsealed items, or create forgeries without the appropriate random string or private key.

2. Anyone may learn the origin, destination(s), and representation of all messages in the underlying telecommunication system and anyone may inject, remove, or modify messages.

**Mail System**

The users of the cryptosystem will include not only the correspondents but a computer called a "mix" that will process each item of mail before it is delivered. A participant prepares a message M for delivery to a participant at address A by sealing it with the addressee's public key Ka, appending the address A, and then sealing the result with the mix's public key K1. The left-hand side of the following expression denotes this item which is input to the mix:

\[ K_1( R_1, K_a( R_0, M ), A ) \rightarrow K_a( R_0, M ), A. \]

The \( \rightarrow \) denotes the transformation of the input by the mix into the output shown on the right-hand side. The mix decrypts its input with its private key, throws away the random string \( R_1 \), and outputs the remainder. One might imagine a mechanism that forwards the sealed messages \( K_a( R_0, M ) \) of the output to the addressees who then decrypt them with their own private keys.

The purpose of a mix is to hide the correspondences between the items in its input and those in its output. The order of arrival is hidden by outputting the uniformly sized items in lexicographically ordered batches. By assumption (1) above, there need be no concern about a cryptanalytic attack yielding the correspondence between the sealed items of a mix's input and its unsealed output - if items are not repeated. However, if just one item is repeated in the input and allowed to be repeated in the output, then the correspondence is revealed for that item.

Thus, an important function of a mix is to ensure that no item is processed more than once. This function can be readily achieved by a mix for a particular batch by removing redundant copies before outputting the batch. If a single mix is used for multiple batches, then one way that repeats across batches can be detected is for the mix to maintain a record of items used in previous batches. (Records can be discarded once a mix changes its public key by, for example, announcing the new key in a statement signed with its old private key.) A mix need not retain previous batches if part of each random string \( R_1 \) contains something - such as a time-stamp - that is only valid for a particular batch.

If a participant gets signed receipts for messages it submits to a mix, then the participant can provide substantial evidence that the mix failed to output an item properly. Only a wronged participant can supply the receipt \( Y (= Inv(K_1)( C, K_1( R_1, K_a( R_0, M ), A )) ) \), the missing output \( X (= K_a( R_0, M ), A ) \), and the retained string \( R_1 \) such that \( K_1( Y ) = C, K_1( R_1, X ) \). Because a mix will sign each output batch as a whole, the absence of an item \( X \) from a batch can be substantiated by a copy of the signed batch.

The use of a "cascade", or series of mixes, offers the advantage that any single constituent mix is able to provide the secrecy of the
correspondence between the inputs and the outputs of the entire cascade. Incrimination of a particular mix of a cascade that failed to properly process an item is accomplished as with a single mix, but only requires a receipt from the first mix of the cascade, since a mix can use the signed output of its predecessor to show the absence of an item from its own input. An item is prepared for a cascade of \( n \) mixes the same as for a single mix. It is then successively sealed for each succeeding mix:

\[
\text{Kn}( \text{Rn}, \text{K}<\text{n}-1>( \text{R}<\text{n}-1>, \ldots, \text{K}2( \text{R}2, \text{K}1( \text{R}1, \text{K}a( \text{R}0, \text{M}), \text{A} ))\ldots)) \rightarrow.
\]

The first mix yields a lexicographically ordered batch of items, each of the form

\[
\text{K}<\text{n}-1>( \text{R}<\text{n}-1>, \ldots, \text{K}2( \text{R}2, \text{K}1( \text{R}1, \text{K}a( \text{R}0, \text{M}), \text{A} ))\ldots) \rightarrow.
\]

The items in the final output batch of a cascade are of the form \( \text{K}a( \text{R}0, \text{M}), \text{A} \), the same as those of a single mix.

Return Addresses

The techniques just described allow participant \( x \) to send anonymous messages to participant \( y \). What is needed now is a way for \( y \) to respond to \( x \) while still keeping the identity of \( x \) secret from \( y \). A solution is for \( x \) to form an untraceable return address \( \text{K}1( \text{R}1, \text{Ax}), \text{K}x \) where \( \text{Ax} \) is its own real address, \( \text{K}x \) is a public key chosen for the occasion, and \( \text{R}1 \) is a key that will also act as a random string for purposes of sealing. Then, \( x \) can send this return address to \( y \) as part of a message sent by the techniques already described. (In general, two participants can exchange return addresses through a chain of other participants, where at least one member of each adjacent pair knows the identity of the other member of the pair.) The following indicates how \( y \) uses this untraceable return address to form a response to \( x \), via a new kind of mix:

\[
\text{K}1( \text{R}1, \text{Ax }), \text{K}x( \text{R}0, \text{M}) \rightarrow \text{Ax}, \text{R}1( \text{K}x( \text{R}0, \text{M})).
\]

This mix uses the string of bits \( \text{R}1 \) that it finds after decrypting the address part \( \text{K}1( \text{R}1, \text{Ax}) \) as a key to re-encrypt the message part \( \text{K}x( \text{R}0, \text{M}) \). Only the addressee \( x \) can decrypt the resulting output because \( x \) created both \( \text{R}1 \) and \( \text{K}x \). The mix must not allow address parts to be repeated - for the same reason that items of regular mail must not be repeated. This means that \( x \) must supply \( y \) with a return address for each item of mail \( x \) wishes to receive. Also notice that conventional as opposed to public key cryptography could be used for both encryptions of \( M \).

With a cascade of mixes, the message part is prepared the same as for a single mix, and the address part is as shown in the following input:

\[
\text{K}1( \text{R}1, \text{K}2( \text{R}2, \ldots, \text{K}<\text{n}-1>( \text{R}<\text{n}-1>, \text{Kn}( \text{Rn}, \text{Ax})\ldots)), \text{K}x( \text{R}0, \text{M}) \rightarrow.
\]

The result of the first mix is

\[
\text{K}2( \text{R}2, \ldots, \text{K}<\text{n}-1>( \text{R}<\text{n}-1>, \text{Kn}( \text{Rn}, \text{Ax})\ldots)), \text{R}1( \text{K}x( \text{R}0, \text{M}) \rightarrow,
\]

and the final result of the remaining \( n-1 \) mixes is

\[
\text{Ax}, \text{R}n( \text{R}<\text{n}-1>, \ldots, \text{R}2( \text{R}1( \text{K}x( \text{R}0, \text{M})))\ldots).
\]

Untraceable return addresses allow the possibility of "certified" mail. They can provide the sender of an anonymous letter with a receipt
attesting to the fact that the letter appeared intact in the final output batch. The address A that is incorporated into a certified letter is expanded to include not only the usual address of the recipient, but also an untraceable return address for the sender. When this return address appears in the output batch of the final mix, it is used to mail the sender a signed receipt which includes the message as well as the address to which it was delivered. The receipt might be signed by each mix.

Digital Pseudonyms

A digital "pseudonym" is a public key used to verify signatures made by the anonymous holder of the corresponding private key. A "roster", or list of pseudonyms, is created by an authority that decides which applications for pseudonyms to accept, but is unable to trace the pseudonyms in the completed roster. The applications may be sent to the authority anonymously, by untraceable mail, for example, or they may be provided in some other way.

Each application received by the authority contains all the information required for the acceptance decision and a special unaddressed digital letter (whose message is the public key K, the applicant's proposed pseudonym) in the case of a single mix, these letters are of the form K1( R1, K ). For a cascade of n mixes, they are of the form Kn( Rn, ..., K2( R2, K1( R1, K ))...). The authority will form an input batch containing only those unaddressed letters from the applications it accepts. This input batch will be supplied to a special cascade whose final output batch will be publicly available. Since each entry in the final output batch of the cascade is a public key K from an accepted applicant, the signed output of the final mix is a roster of digital pseudonyms.

Notification of applicants can be accomplished by also forming a roster for unaccepted applications and then using the technique of certified mail to return a single batch of receipts to both sets of applicants. Of course, repeats must not be allowed within or across batches.

If only registered voters are accepted for a particular roster, then it can be used to carry out an election. For a single mix, each voter submits a ballot of the form K1( R1, K, Inv(K)( C, V )), where K is the voter's pseudonym and V is the actual vote. For a cascade of mixes, ballots are of the form Kn( Rn, ..., K2( R2, K1( R1, K, Inv(K)( C, V )))...). The ballots must be processed as a single batch, as were the letters used to form rosters. Items in the final lexicographically ordered output batch are of the form K, Inv(K)( C, V ). Since the roster of registered voters is also ordered on K, it is easy for anyone to count the votes by making a single pass through both batches at once. Each ballot is counted only after checking that the pseudonym K which forms its prefix, is also contained in the roster and that the pseudonym properly decrypts the signed vote V.

An individual might be known to an organization only by a pseudonym that appears in a roster of acceptable clients. Clients can correspond with the organization via untraceable mail and the organization can correspond with the clients using untraceable return addresses. If applicants identify themselves in their applications, or if they sign applications with pseudonyms that appear in a roster issued by an authority that requires identification, then the organization is assured that the same client cannot come to it under different pseudonyms. Under special circumstances, such as default of payment, a particular pseudonym could be shown to correspond to a
particular application (without revealing any other correspondences) if each mix in turn supplied the appropriate \( R_n \).

**General Purpose Mail Systems**

One way to construct a general purpose, untraceable mail system is to require that every message pass through a cascade. Of course, mixes can operate continuously or periodically, and long messages will be encrypted first and then split into multiple items. In order to hide the number of messages sent, each participant supplies the same number of messages to each batch (some of which might be randomly addressed dummies). In order to hide the number of messages received, each participant privately searches the entire output for messages directed to it.

Such a system may prove too costly for some participants. One way to reduce the cost is to allow mail to be addressed to subsets of participants, such as a local net. Participants that take advantage of such arrangements need search only the mail addressed to a particular subset. Another way to economize is for a participant to send for each batch only the number of dummy messages suggested by a random value (chosen from some suitable distribution), as opposed to always sending the maximum number of messages. This can substantially reduce message traffic and consequently, the size of output batches. While these techniques may open the door to some kinds of statistical attack, the system size that necessitated them may reduce the effectiveness of such attacks.

In a large, general purpose mail system with many mixes, it may be impractical for every message to pass through every mix. In such a case, a sequence of mixes will be selected for each message, perhaps on the basis of network topology or trust. Notice that if a participant can choose mixes it trusts with its traffic volume data as early members of its sequences, then these mixes can discard dummies they receive from the participant and deliver small, fixed-sized batches (padded with dummies) directly to the participant.

A new kind of mix will be presented here that allows a sequence of mixes to be selected for each message. It also (a) hides the number and identity of the mixes a message must pass through, (b) allows incrimination of a mix that does not properly forward items, and (c) makes no distinction between regular mail and mail sent by untraceable return address. It is based on the idea that every item of mail is composed of the same number of fixed-sized blocks.

The operations performed by this new kind of mix are always the same. First it removes the first block and adds a random block \( J \) of junk to the end, to maintain the item's length of \( l \) blocks. Then, using its private key, the mix decrypts the block removed during the first step. This yields a key \( R \), which the mix uses to encrypt each of the \( l \) blocks of the item (using either public-key or conventional cryptography). It also yields the address \( A \) (either of a recipient or of another mix) to which the item will be forwarded.

The left-hand side of the following shows how an item is prepared to pass through a single mix:

\[
K_2( R_2, \ldots, K_{n-1}( R_{n-1}, K_n( R_n, A_x ))) \ldots, R_1( K_x( R_0, M )) \text{ --- > } A_1: [K_{<A_1>}( R_{<A_1>}, A )], [\text{Inv}(R_{<A_1>})( M_1 )], [\text{Inv}(R_{<A_1>})( M_2 )], \ldots [\text{Inv}(R_{<A_1>})( M_{l-1} )] \text{ --- > } A: [M_1], \ldots[M_{l-1}], [R_{<A_1>}( J_{<A_1>} )].
\]

where square brackets show the extent of each block, and the sealed
message $K_a( R_0, M )$ is divided into pieces $M_i$, such that
$K_a( R_0, M ) = M_1, M_2, ..., M_{l-n}$. The $A_1:$ indicates that the
left-hand side is delivered to mix $A_1$, while the $A:$ means that the
right-hand side is delivered to address $A$. Items with the same first
block should be regarded as repeats.

A message prepared to be passed through mixes $A_1$ through $A_n$ has the
form

$$A_1: [K_{A_1}( R_{A_1}, A_2 )], [\text{Inv}(R_{A_1})(K_{A_2}( R_{A_2}, A_3 ))], \ldots,$$
$$[\text{Inv}(R_{A_1})(\text{Inv}(R_{A_2}) \ldots \text{Inv}(R_{A_1})( K_{A_n}( R_{A_n}, A )) \ldots )],$$
$$[\text{Inv}(R_{A_1})( \text{Inv}(R_{A_2}) \ldots \text{Inv}(R_{A_1})( M_1 ) \ldots )], \ldots,$$
$$[\text{Inv}(R_{A_1})( \text{Inv}(R_{A_2}) \ldots \text{Inv}(R_{A_1})( M_{l-n} ) \ldots )] \rightarrow.$$

The result leaving $A_1$ is

$$A_2: [K_{A_2}( R_{A_2}, A_3 )], [\text{Inv}(R_{A_2})(K_{A_3}( R_{A_3}, A_4 ))], \ldots,$$
$$[\text{Inv}(R_{A_2})(\text{Inv}(R_{A_3}) \ldots \text{Inv}(R_{A_2})( K_{A_n}( R_{A_n}, A )) \ldots )],$$
$$[\text{Inv}(R_{A_2})( \text{Inv}(R_{A_3}) \ldots \text{Inv}(R_{A_2})( M_1 ) \ldots )], \ldots,$$
$$[\text{Inv}(R_{A_2})( \text{Inv}(R_{A_3}) \ldots \text{Inv}(R_{A_2})( M_{l-n} ) \ldots )],$$
$$[R_{A_1}( J_{A_1} )] \rightarrow.$$

and the final result leaving $A_n$ is

$$A: [M_1], [M_2], \ldots, [M_{l-n}],$$
$$[R_{A_n}( R_{A_{n-1}} \ldots R_{A_1}( J_{A_1} ) \ldots )], \ldots, [R_{A_n}( J_{A_n} )].$$

An intermediate mix always knows which mix it received its input from-by assumption (2) - but if a mix broadcasts copies of its fixed-size
output batches, then only individual recipient mixes need be able to
recognize their own input in a broadcast batch.

The untraceable return address $x$ sends to $y$ contains the key $K_x$ that $y$
uses to encrypt the message part. It also includes, in the case of a
single mix, what $y$ will use as the first block of the item it submits
to the mix:

$$A_1: [K_{A_1}( R_{A_1}, A_2 )], [M_1], \ldots, [M_{l-1}],$$
$$[R_{A_1}( R_{A_{n-1}} \ldots R_{A_1}( J_{A_1} ) \ldots )], \ldots, [R_{A_1}( J_{A_1} )] \rightarrow.$$

where $K_x( R_0, M ) = M_1, M_2, ..., M_{l-n}$. Only $x$ can decrypt the item
it receives since it created $R_{A_1}$ and $K_x$. When a message is to pass
through $n$ mixes, the untraceable return address contains the first $n$
blocks:

$$A_1: [K_{A_1}( R_{A_1}, A_2 )], [\text{Inv}(R_{A_1})(K_{A_2}( R_{A_2}, A_3 ))], \ldots,$$
$$[\text{Inv}(R_{A_1})(\text{Inv}(R_{A_2}) \ldots \text{Inv}(R_{A_1})( K_{A_n}( R_{A_n}, A_1 )) \ldots )],$$
$$[M_1], [M_2], \ldots, [M_{l-n}] \rightarrow.$$

After being operated on by mix $A_1$ it will have the form

$$A_2: [K_{A_2}( R_{A_2}, A_3 )], \ldots,$$
$$[\text{Inv}(R_{A_2})(\text{Inv}(R_{A_3}) \ldots \text{Inv}(R_{A_2})( K_{A_n}( R_{A_n}, A_1 )) \ldots )],$$
$$[R_{A_1}( M_1 )], [R_{A_1}( M_2 )], \ldots, [R_{A_1}( M_{l-n} )],$$
$$[R_{A_1}( J_{A_1} )] \rightarrow.$$

and the final result leaving $A_n$ is

$$A: [R_{A_n}( R_{A_{n-1}} \ldots R_{A_1}( M_1 ) \ldots )], \ldots,$$
$$[R_{A_n}( R_{A_{n-1}} \ldots R_{A_1}( M_{l-n} ) \ldots )],$$
$$[R_{A_n}( R_{A_{n-1}} \ldots R_{A_1}( J_{A_1} ) \ldots )], \ldots, [R_{A_n}( J_{A_n} )].$$

Summary and Conclusion
A solution to the traffic analysis problem has been presented that allows any single intermediary to provide security for those messages passing through it. In addition, the solution allows messages to be sent or received pseudonymously. Through the notion of a roster of pseudonyms, it also provides some new and interesting kinds of limited anonymity.

Acknowledgements. I owe a great deal to R. Fabry’s outstanding and multifaceted support. Special thanks are due C. Sequin, who has read my work with great care and provided many stimulating discussions. I would also like to thank D. Gusfield, B. Mont-Reynaud, A. Moose, and S. Wecker for their comments and encouragement. The referees have been very helpful.
