Abstract. The elliptic curve primality proving algorithm is one of the fastest practical algorithms for proving the primality of large numbers. Its fastest version, fastECPP, runs in heuristic time $\tilde{O}((\log N)^4)$. The aim of this article is to describe new ideas used when dealing with very large numbers. We illustrate these with the primality proofs of some numbers with more than 10,000 decimal digits.

1 Introduction

The work by Agrawal, Kayal and Saxena [1] on the existence of a deterministic polynomial time algorithm for deciding primality stimulated the field of primality proving at large. As a result, this caused the study and implementation of a fast version of the elliptic curve primality proving algorithm (ECPP). We refer to [2] for a presentation of the method and [13] for the description of the faster version, originally due to J. O. Shallit. Whereas ECPP has a heuristic running time of $\tilde{O}((\log N)^5)$ for proving the primality of N , the new algorithm has complexity $\tilde{O}((\log N)^4)$. This new approach enabled one of us (FM), to prove the primality of numbers with more than 7,000 decimal digits.

Independently, three of us (JF, TK and TW) started to write a new implementation of ECPP in November 2002 which was available by December 2002, and this was improved step by step until the team working in Bonn came up with a set of programs used to prove the primality of $10^{9999} + 33603$ on August 19, 2003.

The two teams decided after this to exchange ideas and comparisons, forming the present article that concentrates on issues regarding distributed implementations of fastECPP and its use in the proving of very large numbers. The theory of fastECPP will be described more fully in the final version of [13].

Our article is organized as follows. Section 2 provides a short description of fastECPP. Section 3 gives two strategies for distributing the computations. Section 4 deals with a faster way of looking for small prime factors of a bunch

*** Projet TANC, Pôle Commun de Recherche en Informatique du Plateau de Saclay, CNRS, École polytechnique, INRIA, Université Paris-Sud.

of numbers at the same time. This part has an independent interest and we think that it could be useful in other algorithms. In Section 5, an alternative to the method of [9, 5] for the root finding in the proving steps of ECPP is described. Section 6 deals with the use of fast multiplication beyond the GMP level in order to speed up all basic multiplications. In Section 7, we describe an *early abort strategy* for limiting the number of steps in ECPP. We conclude with timings on primality proofs for some very large numbers, obtained with either implementation.

2 The fast version of ECPP

Ordinary ECPP is described in [2] and fastECPP in [13]. We sketch the description of the latter, assuming the reader has some familiarity with the algorithm.

We want to prove that N is prime. The algorithm builds a so-called *downrun* that is a sequence of decreasing probable primes N_0, N_1, \dots, N_k such that $N_0 = N$ and the primality of each N_i is sufficient to prove that of N_{i-1} . Theory tells us that we should anticipate a length of $k = O(\log N)$ for the sequence.

If q is an odd prime, put $q^* = (-1)^{(q-1)/2}q$; add to this special primes $-4, -8, 8$ as explained in [13].

The algorithm runs as follows:

[Step 1.]

- 1.1. Find the r smallest primes q^* such that $(\frac{q^*}{N}) = 1$, yielding $\mathcal{Q} = \{q_1^*, q_2^*, \dots, q_r^*\}$.
- 1.2. Compute all $\sqrt{q^*} \bmod N$ for $q^* \in \mathcal{Q}$.
- 1.3. Try all subsets of distinct elements of $\mathcal{S} = \{q_{i_1}^*, q_{i_2}^*, \dots, q_{i_s}^*\}$ of \mathcal{Q} for which $-D = \prod_{q^* \in \mathcal{S}} q^* < 0$, until a solution of the equation

$$4N = U^2 + DV^2 \tag{1}$$

in rational integers U and V is found, which involves computing $\sqrt{-D} \bmod N$ and use Cornacchia's algorithm. When this is the case, let $\{U_1, \dots, U_w\}$ be the different U -values (we have at most $w = 6$ and generally $w = 2$).

[Step 2.] For all U_i 's, compute $m_i = N + 1 - U_i$; if none of these numbers can be written as cN' with c a B -smooth number and N' a probable prime, go to Step 1. If there is a good one, call it m .

[Step 3.] Build an elliptic curve \overline{E} over $\overline{\mathbb{Q}}$ having complex multiplication by the ring of integers of $\mathbf{K} = \mathbb{Q}(\sqrt{-D})$.

[Step 4.] Reduce \overline{E} modulo N to get a curve E of cardinality m .

[Step 5.] Find P on E such that $[N']P = O_E$. If this cannot be done, then N is composite, otherwise, it is prime.

[Step 6.] Set $N = N'$ and go back to Step 1.

Note that what differentiates ECPP from its fast version is Step 1. In Step 1.3, we only consider fundamental discriminants, as a curve with CM by a non-principal order has the same cardinality as one with CM by the principal order.

ECPP is a Las Vegas type algorithm. Its running time cannot be proved rigorously, but only in a heuristic way using standard hypotheses in number theory. When given a number N , it can answer one of three things: “ N is prime”, “ N is composite” or “I do not know”. In the first two of these cases, the answer is definitely correct and there is an accompanying *proof* that can be verified in polynomial time. The problem is in showing that the third case happens with very low probability.

In real life, programs implementing (fast)ECPP should follow this philosophy and never return something wrong. When the third answer is returned, this corresponds very frequently to the fact that the program ran out of precomputed data (such as discriminants, or class polynomials) or used too small factorisation parameters in Step 2. The programmer has to correct this and start again with the number. We never saw a number resisting indefinitely, though we cannot prove none exists.

All algorithms and tricks [11,12] developed over the years for ECPP apply *mutatis mutandis* to the new version. This includes the invariants developed in [6, 4] and the Galois approach for solving the equation $H_D[u](X)$ modulo p (see [9, 5]) needed in Step 3, which favors smooth class numbers.

When dealing with very large numbers (10000 decimal digit numbers, say), every part of the algorithm should be scrutinized again, which includes optimizing the basic routines beyond the current level of GMP. In Step 2., B -smooth numbers are to be identified. The number B is important in the actual running time, and its precise value must be set depending on the algorithm used. See Section 4 below. A new strategy (early abort) is described in section 7. Also, Step 3-4 can be merged, as explained in section 5.

3 First strategies for distribution

Step 1-2 and Step 3-5 are easy to distribute over clusters of workstations. In this section, we give two distribution strategies.

3.1 Strategy 1

The following is easily implemented when all slaves have the same computing power, making it a parallel implementation.

- S1. The master sends to each slave a batch of $\sqrt{q_i^*}$ to compute.
- S2. Each slave computes its batch and sends the results back to the master.
- S3. The master sends all the squareroots to all the slaves, so that each slave can compute any $\sqrt{-D}$ that is needed.
- S4. The master sends batches of D 's to all the slaves. Each slave is responsible for the resolution of (1) and the factorization of the m 's. If one is found, it is sent back to the master which checks the results and restarts a new phase.

S3 needs synchronization and communications.

In S4, load balancing is not easy, since the results are probabilistic in nature (for which D does N split?). A probabilistic answer is to compute beforehand the average number of splitting D 's that can occur. By genus theory, each D with t prime factors has splitting probability $g(-D)/h(-D)$ with $g(-D) = 2^{t-1}$. This suggests to build the whole set of discriminants D in Step 1.3 and to sort them with respect to $(h(-D)/g(-D), D)$. One could also add a criterion describing the difficulty of building the class polynomial $H_D(X)$ later on, maybe using the height of the polynomial (as evaluated in [4]). We send to each slave discriminants $D_{i_1}, D_{i_2}, \dots, D_{i_k}$ in such a way that

$$\sum_j g(D_{i_j})/h(D_{i_j}) \geq 5$$

(the value of 5 is somewhat arbitrary) which corresponds to the fact that on average, 5 values of D will be splitting values. Of course, this quantity should depend on the power of the slave.

3.2 Strategy 2

Another approach would be to set up a complicated system in which the master keeps trace of the work of each slave and decides what kind of work to do at some point. This is easily implemented on the side of the slaves: they wait for a task from the master, do it and send the result back. We now describe a possible implementation of the master.

There are 6 different tasks which the slaves work on:

- T1. Check whether the class number for a discriminant D is good, i.e. is not too big and does not contain a very large prime factor.
- T2. Compute a modular square root $\sqrt{q_i^*}$ modulo N .
- T3. Try to solve (1) for a given D .
- T4. Do trial division for an interval of primes and a batch of m 's and return the factored parts. See Section 4.
- T5. Do a Fermat test.
- T6. Do a Miller-Rabin test.

The master keeps lists of tasks of these six types which at the beginning are all empty. If all task lists are empty the master creates new tasks of type T1. The tasks are sorted according to their priority, T1 having lowest and T6 having highest priority. If a slave requests a new task the master selects from all available tasks one with the highest priority and passes it to this slave. A completed task will create a varying number of new task, e.g. a computed square root (T2) may create many tasks of type T3 whilst a Fermat test (T5) will only on success create a task of type T6. If a certain number of tasks T6 for the same integer are successful one reduction step is finished and pending tasks are cancelled.

4 An optimized test for the divisibility by small primes

Let us first analyze the effect of trial division on the number of pseudo-primality tests (the most time consuming part of our implementation). Suppose we do trial division up to B on a number $N = fR$ where f is only divisible by primes $\leq B$ and R only divisible by primes $> B$. Let us assume that $\log B \leq \sqrt[3]{\log N}$, a condition which is almost always satisfied in practice. Let $p_{\max}(n)$ be the largest prime divisor of n . One can combine the prime number theorem with Rankin's trick and Mertens's theorem [14, 9.1.5 and 9.1.8] and related facts to investigate the sums

$$s = \sum_{\substack{f < x \\ p_{\max}(f) < B}} \pi(x/f)$$

$$l = \sum_{\substack{f < x \\ p_{\max}(f) < B}} \log(f) \pi(x/f)$$

where $\pi(x)$ counts the number of primes below x . Assuming $\log B \leq \sqrt[3]{\log x}$, we find them to be

$$s = \frac{x \exp(\gamma) (\log(B) + O(1))}{\log(x)}$$

$$l = \frac{x \exp(\gamma) (\log(B)^2 + O(\log B))}{\log(x)},$$

where γ is Euler's constant. Since s counts the number of $N < x$ for which R is prime, while l is the sum of $\log(f)$ over such N , one concludes that for a randomly chosen $N \in [(1 - \epsilon)x, x]$ with a fixed positive $\epsilon < 1$ and for $x \rightarrow \infty$, $z \rightarrow \infty$ subject to $\log B \leq \sqrt[3]{\log x}$, the probability that R is prime tends to $\exp(\gamma) \log(B) / \log(N)$ while the expectation value of $\log(l)$ is $\log(B) + O(1)$. By this heuristic argument, one expects the number of pseudo-primality tests for a reduction of fixed size to be proportional to $(\log B)^{-2}$.

We now describe how to perform the trial division in Step 2 more efficiently by doing it on many numbers simultaneously. This is essentially a simplification of the algorithm in [3]. Let N be a (pseudo)prime for which we want to do a reduction step and let m_1, \dots, m_t be the numbers computed in Step 2 (we may choose t of order $\frac{\log N}{2 \log B}$). For simplicity we assume that $t = 2^u$ is a power of two. The following algorithm strips the primes up to B from the numbers m_i :

1. Build the product $P = \prod_{p \leq B, p \text{ prime}} p$ using a binary tree. Unless the bound B is changed this has to be done only once.
2. Compute the product $M = \prod_i m_i$ as follows: Set $m_i^{(0)} = m_i$ and for $a = 1, \dots, u$ successively compute $m_i^{(a)} = m_{2i-1}^{(a-1)} m_{2i}^{(a-1)}$, $1 \leq i \leq 2^{u-a}$. Set $M = m_1^{(u)}$.
3. Compute $\tilde{M} = P \bmod M$ and set $\tilde{m}_1 = \tilde{M}$.

4. Compute $\tilde{m}_i = P \bmod m_i$ as follows: For $a = u, \dots, 1$ compute $\tilde{m}_{2^{i-1}}^{(a-1)} = \tilde{m}_i^{(a)} \bmod m_{2^{i-1}}^{(a-1)}$ and $\tilde{m}_{2^i}^{(a-1)} = \tilde{m}_i^{(a)} \bmod m_{2^i}^{(a-1)}$, $1 \leq i \leq 2^{u-a}$. Set $\tilde{m}_i = \tilde{m}_i^{(0)}$.
5. For $1 \leq i \leq t$ replace repeatedly \tilde{m}_i by $\gcd(m_i, \tilde{m}_i)$ and m_i by $\frac{m_i}{\tilde{m}_i}$ until $\tilde{m}_i = 1$.

Remarks:

Note that for $P < M$ we can save some of the top level computations and the application of the algorithm becomes equivalent to several applications with a smaller u , grouping the m_i appropriately. So we assume that u is chosen such that $P > M$ holds.

If we store the partial products

$$P^{(i)} = \prod_{p \leq \frac{B}{2^i}, p \text{ prime}} p$$

which are computed during the precomputation we can decrease the trial division bound by powers of 2 with no extra effort.

Step 5 can be improved e. g. by replacing \tilde{m}_i by $\gcd(m_i, \tilde{m}_i^2)$ in the iteration.

We now analyze the cost of the algorithm. Let $M(n)$ denote the cost of a multiplication of two numbers of size $\exp(n)$. We assume that the FFT is used and set $M(n) = O(n(\log n)^{1+\epsilon})$. The first step is a precomputation whose cost is $O(B(\log B)^2)$. The cost for the second step is

$$\sum_{k=0}^{u-1} 2^{u-1-k} M(2^k \log N) = O(u 2^u \log(N) (\log(2^u \log N))^{1+\epsilon})$$

since all m_i are of size N . In the fourth step the operation count is the same except that an $n \cdot n$ -multiplication is replaced by an $2n : n$ -division. Since the latter is asymptotically as fast as the former the cost for step 4 is the same as for step 2. Since $P \approx \exp(B)$ the cost of the third step is $O(B(\log(2^u \log N))^{1+\epsilon})$. The last step as described above has complexity $O(2^u (\log N)^2 (\log \log N)^{2+\epsilon})$ since the iteration ends after at most $\log_2 N$ steps each consisting of a division and a gcd. This could be improved by modifying this step but we do not need it here. Note also that in practice this step consists mainly of the first $\gcd(m_i, \tilde{m}_i)$, which with high probability is very small, and the number of iterations also is very small.

Assuming $2^u < \log N$ and neglecting $\log \log$ -terms the time spent in pseudo-primality tests is $O(\frac{(\log N)^3}{\log B})$ for a reduction of size $\log B$ whereas the time for trial division is $O(B + (\log N)^3)$. So it is optimal to choose $B = O((\log N)^3)$ which also implies that the cost for the precomputation can be neglected.

Some remarks about storage and parallelization:

The algorithm above needs a lot of memory; most of it at the end of the computation of P . To reduce the memory requirement we may compute partial

products P_j of the primes below B whose product is P and modify step 3 into computing the residues $P_j \bmod M$ and the modular product of these residues. For this to be efficient the partial products should be larger than M .

For a distributed implementation we propose to split P into as many pieces as slaves are present. Each slave executes steps 2-4 of the algorithm for its own P_j and passes at the end $\gcd(m_i, \tilde{m}_i) = \gcd(m_i, P_j)$ to the master. The master assembles these informations and executes step 5 which in practice is very fast.

For the number $10^{999} + 33603$, the bound B was set to 2^{32} .

5 Computing roots of the Hilbert polynomial modulo p

The run-down sequence contains, among other things, a list of pairs (p, D) , where p is a pseudo-prime and where it is expected that an elliptic curve with complex multiplication by the ring \mathcal{O}_K of integers in $K = \mathbb{Q}(\sqrt{-D})$ can be used to derive the primality of p from the primality of some smaller number. It is necessary to compute an element j_p of \mathbb{F}_p which is the j -invariant of an elliptic curve over \mathbb{F}_p with complex multiplication by \mathcal{O}_K .

We outline the method which was used to perform this step for the run-down sequence of $10^{999} + 33603$. As in [9], the idea is to split this task into several steps, each one involving the determination of the modular solution of an equation of degree ℓ_i , where the ℓ_i are the prime factors of the class number h of K . One difference is that [9] tries to compute a sequence of polynomials which define a sequence of intermediate fields terminating in the Hilbert class field L of K . By contrast, the implementation which was used for $10^{999} + 33603$ constructs methods to reduce elements x of the intermediate fields modulo an appropriate prime ideal over p , increasing the subfield in each step. The element x is given by floating point approximations to its conjugate algebraic numbers. Thus, the sequence of intermediate fields occurs in both methods but otherwise the language used is somewhat different, making it difficult to explain to what extent the methods are similar. Since the available space is not sufficient for a careful description of the new method, we give a short example explaining how it works in the case $p = 479$, $D = 335$.

The program chooses the modular invariant $x = x_{13}$ from [2, 2.7.1] and a precision of 32 bit is sufficient for the floating point calculations. The class group of K , and therefore $\text{Gal}(L/K)$, is cyclic of order 18. The program has selected a generator σ of the Galois group, and has computed the complex numbers $\sigma^i(x)$. It has then decided to choose the prime ideal $\mathfrak{p}_o \subset \mathcal{O}_K$ such that

$$(a + b\sqrt{-D}) \bmod \mathfrak{p}_o = \frac{1}{2} \left(([2a] + 12 \left[\frac{2b}{\sqrt{D}} \right]) \bmod p \right), \quad (2)$$

where $\sqrt{D} = 18.30300521772312668$ is the positive square root of D , the subexpressions in square brackets are in real life floating point numbers which will be rounded to nearest integers, and the factor 12 in the second summand is of course a square root of $-D \bmod p$.

The Hilbert class field has unique subfields L_1 and L_2 of degrees 2 and 3 over K . The program knows that the genus field L_1 , which is the largest subfield of L which is Abelian over \mathbb{Q} , is given by $L_1 = K(\sqrt{5})$. It decides to work with the prime ideal $\mathfrak{p}_1 \subseteq \mathcal{O}_{L_1}$ such that, for each element z of L_1 given by a complex floating point approximation to z and $\sigma(z)$, we have

$$z \bmod \mathfrak{p}_1 = \frac{1}{2} \left(((z + \sigma(z)) \bmod \mathfrak{p}_o + 196((z - \sigma(z))\sqrt{5} \bmod \mathfrak{p}_o)) \right), \quad (3)$$

where $\sqrt{5} = 2.23606798$ and the factor 196 in the second summand is of course a modular square root of $1/5 \bmod p$. The reductions modulo \mathfrak{p}_o occurring in this formula are computed by the program using (2).

It is more difficult to describe a prime ideal $\mathfrak{p}_2 \subset \mathcal{O}_{L_2}$ with $\mathfrak{p}_2 \cap \mathcal{O}_K = \mathfrak{p}_o$ in a way which is suitable for calculations. The program considers

$$x_2 = \sum_{i=0}^5 \sigma^{3i}(x),$$

which is an algebraic integer. We have

$$\begin{aligned} x_2 &= -60.2484307 + 78.0404771\sqrt{-1} \\ \sigma(x_2) &= -14.7805113 - 15.4588718\sqrt{-1} \\ \sigma^2(x_2) &= -10.4710580 + 1.47891293\sqrt{-1}. \end{aligned}$$

Note that $\sigma^i(x_2)$ depends only on $i \bmod 3$. The program computes a complex floating point approximation to the minimal polynomial of x_2 over K and finds, using (2) to reduce polynomial coefficients modulo \mathfrak{p}_o , that this polynomial is congruent to $T^3 + 283T^2 + 226T + 108$ modulo \mathfrak{p}_o . It finds that 341, 395 and 418 are the roots of this polynomial modulo p and decides to work with the prime ideal $\mathfrak{p}_2 \subseteq L_2$ such that $x_2 \equiv 341 \pmod{\mathfrak{p}_2}$. It computes coefficients $v_i \in \mathbb{F}_p$, $0 \leq i < 3$, such that

$$z \bmod \mathfrak{p}_2 = \sum_{i=0}^2 v_i \left(\left(\sum_{j=0}^2 \sigma^{i+j}(x_2) \sigma^j(z) \right) \bmod \mathfrak{p}_o \right), \quad (4)$$

where in practice the reduction mod \mathfrak{p}_o is carried out using (2). For this to be possible, it is necessary that x_2 generates a normal basis of \mathcal{O}_{L_2} over \mathcal{O}_K after localisation at \mathfrak{p}_o . The program will abort if this assumption fails. This does not happen in this example, nor did it ever happen during the calculations for $10^{9999} + 33603$. But it should be possible to construct examples of failure of the program, although it is very unlikely for this to happen in practice. In order to determine the coefficients of (4), it is also necessary that the modular roots ξ_i of the minimal polynomial have been ordered in such a way that $\xi_i = \sigma^i(x_2) \bmod \mathfrak{p}_2$. The choice of ξ_0 is of course free, since a different ξ_0 only gives a different \mathfrak{p}_2 . But the order of the other modular zeros is no longer free and the program has to compute them in the correct order. We will describe in a different

paper how this is done without a major increase of the required precision, where of course the order of the cyclic extension will often be larger than 3. Once the ξ_i have been computed in the correct order, it is a linear algebra task to determine the v_i such that (4) holds for $z = \sigma^k(x_2)$, $0 \leq k < 3$. In the given example, the result is

$$v_0 = 417 \quad v_1 = 170 \quad v_2 = 393.$$

The compositum $L_3 = L_1 L_2$ has degree 6 over K , and there is a unique prime ideal $\mathfrak{p}_3 \subset \mathcal{O}_{L_3}$ such that $\mathfrak{p}_3 \cap \mathcal{O}_{L_i} = \mathfrak{p}_i$ for $i \in \{1; 2\}$. If an element z of \mathcal{O}_{L_3} is given by complex floating point approximations to $\sigma^i(z)$, where $0 \leq i < 6$, then

$$z \bmod \mathfrak{p}_3 = \frac{1}{2}(z_o \bmod \mathfrak{p}_2 + 196(z_1 \bmod \mathfrak{p}_o)), \quad (5)$$

where the $z_{0,1} \in L_2$ are given by

$$\begin{aligned} \sigma^i(z_0) &= \sigma^i(z) + \sigma^{i+3}(z) \\ \sigma^i(z_1) &= \sqrt{5}(\sigma^i(z) - \sigma^{i+3}(z)), \end{aligned}$$

and $z_i \bmod \mathfrak{p}_2$ is computed by (4).

The program now computes a complex floating point approximation to $\sigma^i(P)$ for $0 \leq i < 6$, where P is the minimal polynomial of x over L_3 . Using (5), it finds P to be congruent to $T^3 + 151T^2 + 434T + 346$ modulo \mathfrak{p}_3 . The largest rounding error was 0.000488281. One modular root of P is 153. This means that there exists a prime ideal \mathfrak{p} dividing \mathfrak{p} in \mathcal{O}_L such that $x \equiv 153 \bmod \mathfrak{p}$. From x , one can compute the j -invariant of an elliptic curve with complex multiplication by \mathcal{O}_K using the formula

$$j = \frac{(x^4 + 7x^3 + 20x^2 + 19x + 1)^3(x^2 + 5x + 13)}{x}.$$

With $x = 153 \bmod 479$, this gives $j = 307 \bmod 479$.

Calculating the minimal polynomial of x over K and reducing it modulo \mathfrak{p}_o , using (2), turns out to be impossible with 32 bit precision. If 48 bits are used, the largest rounding error is 0.0195312. Of course, this increase of the required precision is due to the fact that the theory of the genus field was not used.

The program used for $10^{9999} + 33603$ was a development version, with many possible optimisations not yet implemented. For instance, it is clear from the above example that not all Weber class invariants were implemented.

6 Use of the Fastest Fourier Transform in the West

For most of the calculations for $10^{9999} + 33603$, we used integer multiplication using the Fastest Fourier Transform in the West (see <http://www.fftw.org> and [7, 8]). To square a number of size 10^{9999} , it was broken into 1661 digits of size 20 bit. These digits were inserted into an array of 3600 double variables, which was then transformed using the functions provided by `libfftw3.a`, the

result was squared and transformed back also using `libfftw3.a`. The same thing can be done for a product of two different factors, and if a factor occurs often then its Fourier transform may be precalculated and stored to reduce the time for a multiplication by this factor to the time for a squaring. It is easy to see that this choice of parameters does not guarantee exact results. Therefore, we also calculated a 32-bit checksum. If the checksum test indicates an error, the multiplication is recalculated using the GMP function. In the case of the $p10000$, these recalculations appear to be rare, if they occur at all. Of course, even the checksum does not make this multiplication method rigorous.

We used this fast multiplication both for primality tests and for the calculation of modular square roots in the calculation of the run down sequence. While a modular square root can be checked, and the calculation repeated if necessary, there appears to be no way to detect a false negative result of a Miller-Rabin test. Therefore, by using this method we accepted a small but probably positive probability of a prime number being declared composite by mistake.

The following benchmark results were obtained on an 800-MHz Athlon, using version 4.1.1 of `libgmp.a`, version 3.0 of `libfftw3.a`, and $10^{9999} + 33603$ as the input number:

- One call to the GMP function `mpz_probab_prime_p` with second argument equal to 1, which means that one Fermat and one Rabin-Miller pseudo-primality test is carried out: 317 seconds user time.
- A Rabin-Miller test using 2 as base, and using Montgomery modular multiplication [10] and the GMP functions: 149 seconds.
- A similar program, but using `libfftw3.a` for multiplications: 56 seconds.

The advantage of using `libfftw3.a` could perhaps be reduced if GMP allowed for a way to precalculate Fourier and Toom-Cook transforms of frequently used factors. It is difficult to predict whether this is sufficient to achieve the speed of a multiplication subroutine which is optimized for speed at the expense of producing sometimes (albeit rarely) a false result.

7 The early abort strategy

The idea behind this strategy is to force the new candidate N' in Step 2. to satisfy $N/N' \geq 2^\delta$ for some (small) integer value $\delta = \delta(N)$, with the hope to decrease the number of steps and thereby the number of proving steps. Of course, this might slow down the search for N' a little bit and some optimization is necessary. Yet it appeared critical when used in the primality proof of $10^{9999} + 33603$, when it was first implemented and used.

In FM's implementation, the following value for the lower bound on $\delta(N) = b(N) - b(N')$ was used, where $b(x)$ denotes the number of bits of integer x :

$b(N) \leq$	1000	2500	5000	7500	10000	15000	∞
$\delta(N)$	0	5	10	15	20	25	30

The following data were gathered (with the mpi program to be described). The first column contains the time without EAS, the second with. The line H_D stands for the time needed to compute the polynomials representing the class field, as in [9]; CZ is the time needed for the special variant of the Cantor-Zassenhaus algorithm using a trick of Atkin (using roots of unity modulo N); the number of steps in the *downrun* is then given, and the last lines contain the maximal value for h , before the mean value.

Number	$10^{2999} + 1887$		$10^{3999} + 4771$		$10^{4999} + 22669$	
Steps 1-2	81 h	58 h	280 h	164 h	716 h	476 h
Steps 3-5	26 h	26 h	76 h	86 h	209 h	261 h
H_D	1680 s	4880 s	4497 s	7317 s	3 h	5 h
CZ	22 h	22 h	63 h	75 h	179 h	234 h
# steps	436	358	597	437	734	512
max h	1968	2336	2184	2432	3400	4000
\overline{h}	86	116	120	164	152	272

The restriction one puts on m and thus on D tends to make D and h larger than in the plain case. This can have an impact on the time for computing H_D , and also on the proving part. In the first phase, fewer N' are ever tested for probable primality, though more must be produced. EAS indeed decreases the number of steps, which tends to decrease the total time for the 1st phase, the 2nd being constant or increasing a little. In any case, a strategy yielding a factor of 2 in the total running time is certainly worthwhile.

8 Some large primality proofs

8.1 The first records of fastECP

We begin with some data from FM's implementation that uses MPI on top of his `ecpp` program, and implementing Strategy 1. All computations were done on a cluster of 6 biprocessor Xeon at 2.66 MHz. We took the following numbers from the tables of P. Leyland*. These are numbers of the form $x^y + y^x$. WCT stands for *wall clock time* and includes the time wasted by the distribution process (waiting time of the slaves, typically). The line "Checking" indicates the time needed to check the certificate. Note that the time for this should be $\tilde{O}((\log N)^3)$ and this is compatible with the timings given.

All numbers were proven in 2003. The "when" line indicates the elapsed human dates in big endian notation.

The first number was dealt with an experimental program that turned out to spend too much time in the $\sqrt{-q^*}$ computations. As a matter of fact, a value of $r = 4000$ was used. This led to proceed by chunks of 400 squareroots from a total of 4000, adding 400 more if this was not enough. All discriminants with $D \leq 10^8$, $h \leq 6000$ (later increased to 8000) and the largest prime factor of h

Table 1. Some large numbers proven with FASTECPP.

not exceeding 200 were decided to be usable. A look at column 3 compared to 4 justifies the claim of complexity of $\tilde{O}((\log N)^4)$. The 8046dd number was done after the announcement of the proof of $10^{9999} + 33603$ (see next section), and EAS was not used for this. The 10041dd number was finished on December 20, 2003, well after the one to be described in the next section. This was the first use of EAS for this implementation.

8.2 A new frontier

Let us turn our attention to the barrier-breaking number $10^{9999} + 33603$, whose primality was verified by JF, TK with the help of TW.

The calculations were done using two programs, a pvm program producing the sequence of discriminants, group orders and their prime number factorization (called a run down sequence in what follows), and the second program calculating the elliptic curves.

The calculation of a run down sequence was started on July 17, 2003 on six 900MHz PIII CPUs. On July 21, the computation was moved to 12 nodes of parnass2, the LINUX cluster built at the Scientific Computing Institute in Bonn. 4 of these nodes had two 800MHz CPUs, the other nodes were double PII/400MHz computers. At 8550 digits (on July 30) and 8286 digits (on July 31) we interrupted these calculations to replace the program by a faster version, using the Fastest Fourier Transform in the West in the way explained above. This improvement resulted by a speedup by a factor of about 2. On August 5, we reached 6574 digits. On August 8, we stopped the program at 3256 digits. The final calculations for the run down sequence took about 8 hours on eight 800MHz CPUs. The total CPU time to produce the run down (i.e., without calculating the elliptic curves) was estimated to 234.5 days on a 1GHz Pentium.

The CPU time spent for the actual certificates is more difficult to estimate, since the program for this step was still under development when the calculation of the run down sequence started, and since these calculations were done in heterogeneous environment. We estimate that it would have taken less than 140 days on a single 800MHz Athlon CPU.

The certificate is available as:

`ftp://ftp.math.uni-bonn.de/pub/people/franke/p10000.cert`

9 Conclusions

We have described some new ideas to speed up practical primality proving of large numbers using fastECP. These ideas need more testing and improvements. We hope that this will serve as benchmarks and motivations for the study of other primality proving algorithms as well.

Acknowledgments. Thanks to A. Enge for some useful discussions about this work and for his careful reading of the manuscript. The authors of the certificate for $10^{9999} + 33603$ would like to thank the Scientific Computing Institute at Bonn University for providing the parallel computer which produced the downrun. One of us (J. F.) would also like to thank G. Zumbusch for pointing out the existence of `libfftw3.a` to him. Thanks also to D. Bernstein for sending us his remarks on a preliminary version and to the referees that helped clarify some points.
